Structured Resonant Coupling (SRC)

A Testable Framework for Temporally Structured Field–Medium Interaction

Author: Mark Kacirek
Date: March 2026
Version: Level 1 – Conceptual Framework (V2)

Abstract

Structured Resonant Coupling (SRC) defines a falsifiable experimental framework to test whether temporally structured electric field excitation, combined with passive frequency-dependent phase-selective feedback, can produce reproducible and operationally distinguishable response regimes in relaxation-dominated electromagnetic systems.

Where conventional resonance optimization is typically performed in the frequency domain through impedance matching and steady-state phase alignment, SRC investigates whether time-resolved excitation structuring—coordinated with intrinsic medium relaxation dynamics—introduces measurable differences in phase stability, impedance variance, and transient power distribution.

The framework introduces no new physical principles and operates entirely within classical electromagnetic and circuit theory. Its contribution lies in formalizing temporal excitation architecture as an experimentally controllable variable and defining quantifiable order parameters under matched boundary conditions.

Explicit falsification criteria are provided. A separate technical extension contains full parameter derivations, architectural specifications, and implementation details.

Independent replication and critical evaluation are encouraged.

This framework does not assert energy amplification, violation of conservation laws, or non-classical electromagnetic behavior.

1. Executive Summary

Modern electrochemical and plasma-interacting systems are typically driven by stationary periodic excitation signals. While frequency and duty cycle are commonly optimized, the temporal architecture of excitation is rarely treated as a structured variable in itself.

The central problem addressed in this work is whether the temporal organization of excitation—beyond simple periodic drive—can measurably influence interfacial dynamics, transient response behavior, and system-level efficiency.

Structured Resonant Coupling (SRC) proposes that excitation signals composed of multiple temporally coordinated components—carrier, slow modulation, and phase-synchronized spike elements—may alter coupling behavior within reactive systems when compared to conventional stationary excitation.

The potential utility of this approach lies not in energy amplification, but in improved control of dynamic system response, potentially affecting efficiency, stability, and transient characteristics in electrochemical or plasma-based processes.

This document provides:

- The mathematical and physical rationale underlying the SRC framework
- A comparative experimental architecture (System A vs. System B)
- A falsifiable hypothesis and defined measurement criteria

An experimental setup has been designed to enable controlled comparison between stationary and temporally structured excitation under identical geometric and measurement conditions.

All implementation details, extended theoretical derivations, and supplementary material are available in an openly accessible technical document accompanying this publication.

The objective is independent verification, replication, and critical evaluation.

SRC investigates whether temporal waveform structure and passive phase shaping define a distinct, measurable operating regime.

Potential and Relevance

If experimentally supported, the SRC framework would not imply new physical principles. Its relevance would lie in identifying temporal excitation architecture as a practically relevant design variable in relaxation-dominated systems.

Specifically, it would suggest that coordinated time-domain structuring of excitation, combined with passive frequency-dependent phase shaping, may influence phase stability and impedance consistency under defined parameter conditions.

Such a result would refine resonance optimization practice by introducing time-domain organization as an additional experimentally controllable dimension beyond steady-state frequency tuning.

If no statistically significant differentiation is observed under controlled conditions, the framework yields a clear null result: temporally structured excitation does not produce measurable effects beyond classical resonance behavior in the tested regime.

2. Scientific Context and Open Question

2.1 Classical Resonance Optimization

Resonant behavior in electromagnetic systems is conventionally analyzed in the frequency domain. Under steady-state excitation, system performance is characterized through impedance matching, amplitude response, and phase relations determined by reactive balance between electric and magnetic energy storage.

In linear systems, resonance occurs when inductive and capacitive reactances compensate, leading to characteristic impedance minima and predictable phase behavior. Optimization strategies therefore focus primarily on frequency tuning, quality factor adjustment, and minimization of dissipative losses.

In practical systems involving dielectric or electrochemical media, resonance behavior remains governed by these principles. However, such media exhibit finite relaxation times associated with dipole reorientation, interfacial polarization, or transient conduction processes. As a result, effective permittivity and impedance may evolve dynamically under non-stationary excitation.

Steady-state resonance analysis implicitly assumes time-invariant parameters. When excitation is temporally structured—particularly in pulsed or multi-component waveforms—this assumption may become incomplete, as reactive balance may evolve within individual excitation cycles.

2.2 Open Question

The present work addresses the following question:

Can temporally structured excitation, when combined with passive phase-selective feedback, define a measurable operational regime that differs from classical steady-state resonance optimization in systems with finite relaxation dynamics?

More specifically:

If excitation waveform timing is coordinated with intrinsic medium time scales, and if feedback pathways selectively shape phase relationships within defined frequency bands, does this reduce phase variance and modify reactive energy exchange in a reproducible manner?

This question does not challenge established electromagnetic theory. Instead, it examines whether time-resolved organization of excitation and feedback introduces experimentally distinguishable behavior in driven nonlinear systems.

The investigation is therefore positioned not as a claim of new physics, but as a structured test of whether time-domain organization constitutes a meaningful design dimension beyond conventional frequency-domain tuning.

3. Core Concept of Structured Resonant Coupling (SRC)

The SRC framework is based on the interaction of three coupled elements:

1. Temporally structured field excitation
2. Passive phase-selective feedback
3. Responsive medium dynamics

The central hypothesis is that these elements, when operating within compatible time scales, may define a dynamical regime distinguishable from conventional steady-state resonance behavior.

3.1 Temporally Structured Excitation

In conventional resonance-driven systems, excitation is typically treated as either sinusoidal or as simple pulsed stimulation. Frequency is the dominant design parameter, and waveform structure is often secondary.

In contrast, SRC treats waveform composition and internal timing as primary variables.

Temporally structured excitation refers here to waveforms that contain multiple coordinated time-domain components, such as:

- A primary oscillatory carrier component
- Slower modulation features
- Short-duration transient elements

The purpose of this structuring is not increased amplitude or power density. Rather, it introduces controlled temporal features whose durations and repetition rates may interact with intrinsic time scales of the driven medium.

When excitation features occur on time scales comparable to medium relaxation times, the effective reactive balance between electric and magnetic energy storage may evolve within a cycle. Under such conditions, waveform timing becomes physically relevant rather than incidental.

SRC therefore shifts focus from pure frequency alignment to the coordination of excitation timing with intrinsic system dynamics.

3.2 Passive Phase-Selective Feedback

In linear steady-state resonance, phase behavior is determined by impedance and frequency offset. However, in time-structured regimes, phase relationships can evolve dynamically within each excitation cycle.

SRC introduces a passive, frequency-dependent feedback pathway—typically realized through an RLC network—whose role is not amplification but phase shaping.

This pathway:

- Selectively influences phase within a defined frequency band
- Introduces predictable phase shifts based on classical transfer functions
- Operates without active control or external regulation

The hypothesis is not that feedback creates energy or enforces stability by control. Rather, the frequency-dependent phase response may constrain phase drift when interacting with structured excitation.

In this framework, phase stability becomes a measurable system property rather than a by-product of frequency tuning.

3.3 Responsive Medium Dynamics

Many driven systems involve media with finite relaxation times. Examples include:

- Polar dielectrics
- Electrochemical interfaces
- Ionic conduction environments

Such media exhibit:

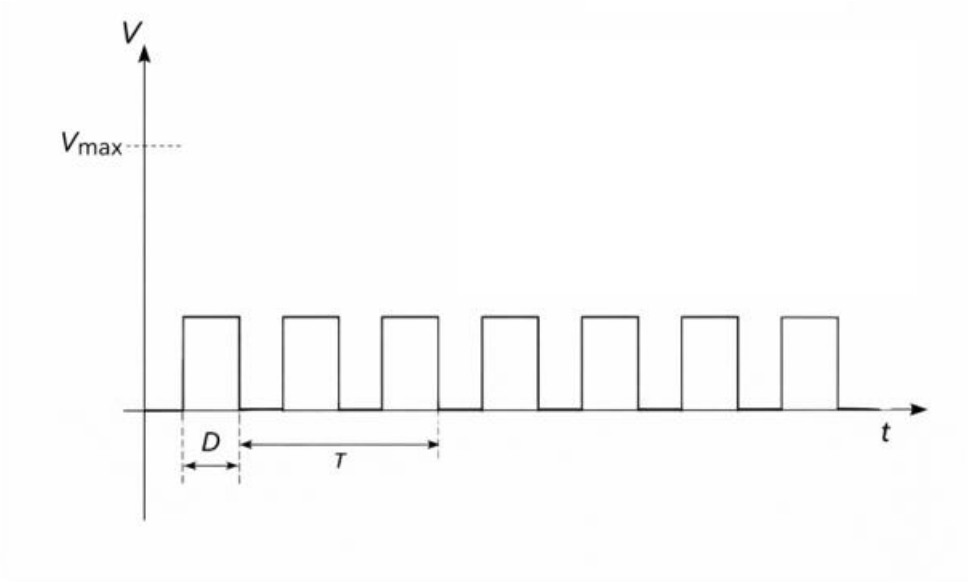
- Frequency-dependent permittivity
- Polarization build-up over finite time scales
- Transient conduction effects

Under temporally structured excitation, these intrinsic time scales may interact with waveform features.

If excitation timing is significantly faster than relaxation, the medium may respond only to averaged fields.
If significantly slower, the system behaves quasi-statically.
However, when excitation structure approaches the characteristic relaxation time, coupling effects may become more sensitive to phase alignment and timing.

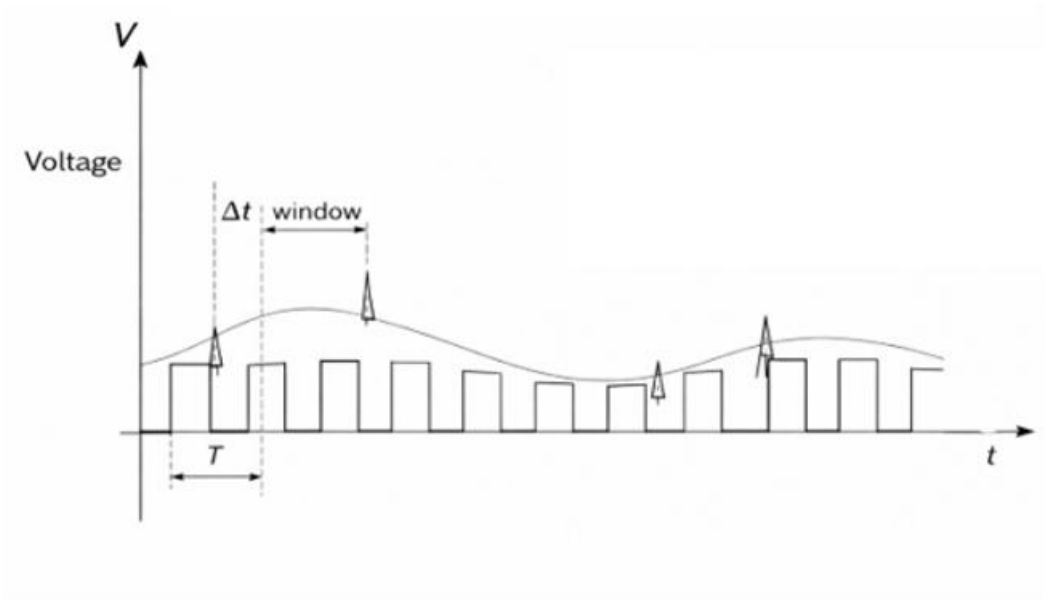
SRC therefore models the medium not as a static load, but as a dynamic participant in reactive energy exchange.

System A – Simple Periodic Excitation



- constant carrier frequency (f_c)
- Fixed duty cycle (D)
- Constant amplitude (V_max)
- No temporal structuring

System B – Temporally Structured Excitation



Structured excitation components:

- Carrier (f_c)
- Slow envelope modulation
- Phase-synchronized spike component

Conceptual Integration

The core of SRC lies in the coordinated interaction of:

- Time-domain waveform structure
- Frequency-dependent phase shaping
- Intrinsic medium relaxation

The framework does not assert that such interaction necessarily produces novel behavior. It asserts that this regime is experimentally definable and testable.

If structured excitation and passive feedback align with intrinsic system time scales, the resulting dynamical state may exhibit:

- Reduced phase variance
- Increased impedance stability
- More consistent reactive power exchange

If not, the system remains fully described by classical resonance analysis.

4. Minimal Physical Model

The SRC framework remains entirely within classical electromagnetic and circuit theory. This section provides a minimal physical formulation explaining why temporally structured excitation combined with passive phase-selective feedback may plausibly influence dynamical stability in relaxation-dominated media.

The objective is not to derive a new theory, but to formalize the coupling between excitation timing, reactive balance, and medium response in time-resolved form.

4.1 Dynamic Capacitance and Time-Dependent Permittivity

In conventional circuit analysis, capacitance is treated as constant:

$$C = \varepsilon_0 \varepsilon_r \frac{A}{d}$$

However, in dielectric or electrochemical systems exhibiting finite relaxation times τ, permittivity becomes frequency-dependent and, under non-stationary excitation, effectively time-dependent.

For excitation components whose duration approaches the intrinsic relaxation time of the medium, polarization does not instantaneously follow the applied field. In the time domain, this can be expressed as:

$$C_{\text{eff}}(t) = \varepsilon_0 \varepsilon(t) \frac{A}{d}$$

where $\varepsilon(t)$represents the evolving polarization state.

Under temporally structured excitation, the reactive balance between electric and magnetic energy storage may therefore vary within an excitation cycle. The system cannot be treated as strictly time-invariant.

This observation motivates examining whether coordinated waveform timing influences phase behavior when reactive parameters evolve dynamically.

4.2 Time-Dependent Reactive Condition

In a classical RLC system with constant parameters, the resonance condition is:

$$f_0 = \frac{1}{2\pi\sqrt{LC}}$$

If capacitance becomes time-dependent due to medium relaxation, the instantaneous reactive balance can be expressed formally as:

$$f_0(t) = \frac{1}{2\pi\sqrt{LC_{\text{eff}}(t)}}$$

This does not imply that resonance “moves” arbitrarily. Rather, it highlights that under structured excitation interacting with intrinsic time scales, reactive alignment may evolve within a cycle.

If excitation timing and feedback phase response align with this evolving reactive state, phase drift may be reduced. If misaligned, phase variance may increase.

The SRC hypothesis examines whether structured excitation combined with frequency-dependent passive feedback can better maintain alignment with the instantaneous reactive balance than steady-state tuning alone.

4.3 Phase Alignment as an Order Parameter

In driven electromagnetic systems, phase difference between voltage and current reflects reactive energy exchange.

Define:

$$\Delta\phi(t) = \phi_V(t) - \phi_I(t)$$

Over a finite observation interval T, define:

Mean phase:

$$\Delta\bar{\phi}$$

Phase variance:

$$\sigma^2(\phi) = \frac{1}{T}\int_0^T (\Delta\phi(t) - \Delta\bar{\phi})^2 dt$$

Within SRC, phase variance $\sigma(\phi)$is treated as an operational indicator of dynamical stability.

Classical resonance theory predicts specific phase values at steady-state. However, under temporally structured excitation interacting with relaxation dynamics, phase may fluctuate within each cycle.

The hypothesis is that passive phase-selective feedback may reduce $\sigma(\phi)$within defined parameter windows.

4.4 Operational Definition of the Coherence Index (KCI)

To quantify the temporal consistency of power exchange under non-stationary excitation, a normalized scalar descriptor termed the Coherence Index (KCI) is introduced.

Instantaneous power is defined as:

$$P(t) = V(t)I(t)$$

Over a defined observation interval T, the Coherence Index is given by:

$$KCI = \frac{\left| \int_0^T P(t)\, dt \right|}{\int_0^T \left| P(t) \right|\, dt}$$

By construction:

$$0 \leq KCI \leq 1$$

Interpretation

- $KCI \to 1$: power transfer maintains consistent sign and stable phase alignment over time.
- Lower values indicate increased sign reversals or fluctuating reactive exchange.

The normalization ensures independence from absolute power scaling.
If voltage and current amplitudes are proportionally increased while preserving phase structure, the ratio remains invariant.

KCI therefore isolates temporal sign consistency and phase alignment behavior rather than absolute energy magnitude.

It does not represent "coherent energy" as a separate physical entity.
It is a bounded descriptor of temporal consistency in reactive power exchange.

KCI approaches unity when instantaneous power maintains consistent sign and stable phase alignment.

Relation to Classical Metrics

Unlike steady-state power factor, which is defined under sinusoidal conditions, KCI is applicable to non-stationary, multi-component excitation waveforms.

It serves as an operational bridge between:

- time-domain waveform structure
- evolving phase relationships
- measurable power consistency

Within the SRC framework, KCI provides a compact order parameter linking structured excitation, passive feedback, and medium relaxation behavior.

Section Summary

The minimal model shows that:

- Media with finite relaxation times introduce effective time dependence in reactive parameters.
- Temporally structured excitation may interact with these intrinsic time scales.
- Passive RLC feedback shapes phase behavior in a frequency-dependent manner.
- Phase variance and KCI provide measurable order parameters linking theory and experiment.

The next section translates this physical plausibility into quantitatively defined hypotheses.

5. Quantitative Hypotheses

Building on the minimal physical formulation presented in Section 4, the SRC framework defines explicit, testable hypotheses by which temporally structured excitation combined with passive phase-selective feedback can be evaluated.

All comparisons are performed between:

- System A (Baseline): conventional excitation without feedback
- System B (Structured): temporally organized excitation with passive RLC feedback

under strictly matched geometric, material, thermal, and average input power conditions.

The following hypotheses define measurable deviations that must exceed statistical uncertainty to support the SRC framework.

5.1 H1 – Reduction in Phase Variance

From Section 4.3, phase variance $\sigma(\phi)$ is treated as an operational order parameter reflecting dynamical phase stability.

Hypothesis H1:
System B exhibits a statistically significant reduction in phase variance relative to System A under matched conditions.

The anticipated magnitude of reduction is expected to lie within a moderate range (approximately 10–30%) within defined parameter windows. However, no fixed threshold is imposed a priori.

Statistical requirement:
An observed reduction must:

- Exceed 3σ measurement uncertainty
- Remain reproducible across ≥ 10 independent trials
- Persist under strict average power matching

Null condition:
No statistically significant difference in phase variance between configurations.

5.2 H2 – Stabilization of Impedance Characteristics

As discussed in Section 4.2, reactive balance may evolve dynamically when excitation interacts with medium relaxation behavior.

If structured excitation better aligns with this evolving reactive condition, impedance characteristics may exhibit improved stability.

Hypothesis H2:
System B exhibits statistically significant improvement in impedance stability relative to System A.

Operational indicators include:

- Reduced variability in resonance minimum frequency
- Reduced spread in impedance minima across repeated trials

An anticipated effect magnitude in the range of 10–25% may occur under defined parameter windows, though no fixed numerical threshold is imposed.

Statistical requirement:
Observed improvements must:

- Exceed 3σ uncertainty
- Remain reproducible across repeated trials
- Persist under matched thermal and power conditions

Null condition:
Observed differences remain within experimental uncertainty.

5.3 H3 – Increase in Coherence Index (KCI)

Section 4.4 introduced the Coherence Index (KCI) as a bounded scalar descriptor of temporal consistency in power exchange.

If structured excitation combined with passive feedback improves phase alignment, KCI should increase relative to baseline.

Hypothesis H3:
System B exhibits a statistically significant increase in KCI relative to System A.

The anticipated magnitude of increase is expected to lie within approximately 10–30% under defined parameter windows, though this serves as a calibrated expectation rather than a strict criterion.

Statistical requirement:
The increase must:

- Exceed 3σ measurement uncertainty
- Be reproducible across ≥10 independent trials
- Persist under strict average power matching

Null condition:
No statistically significant increase in KCI.

5.4 Exclusion of Trivial Explanations

Observed differences do not support the SRC hypothesis if they can be fully attributed to:

- Differences in RMS voltage or average input power
- Classical steady-state RLC transfer characteristics
- Thermal drift or temperature gradients
- Electrode aging or surface modification
- Instrumentation bandwidth limitations or measurement artifacts

All comparisons must therefore be performed under strict parameter control and verified power equivalence.

5.5 Expected Magnitude and Interpretation

The SRC framework anticipates moderate effect sizes rather than extreme deviations.

As a calibrated expectation:

- Differences below ~10% may be considered negligible in practical relevance.
- Differences within ~10–30% would be consistent with the minimal physical model.
- Differences substantially exceeding ~50% would suggest mechanisms beyond the minimal model and require additional analysis.

These ranges define interpretative guidance rather than proof thresholds.

Section Summary

Section 4 established physical plausibility within classical electromagnetic and circuit theory. Section 5 defines measurable consequences under controlled experimental conditions.

If statistically significant and reproducible differentiation between System A and System B is not observed under matched conditions, the SRC hypothesis is not supported.

The indicated ranges represent calibrated expectations derived from order-of-magnitude reasoning rather than validated measurements.

6. Experimental Comparison Framework

The SRC hypothesis is evaluated through a controlled comparative design involving two otherwise identical systems. The experimental objective is not performance maximization but differentiation under matched conditions.

The design isolates the influence of temporally structured excitation and passive phase-selective feedback while keeping all other parameters constant.

6.1 System A – Baseline Configuration

System A represents conventional excitation without feedback.

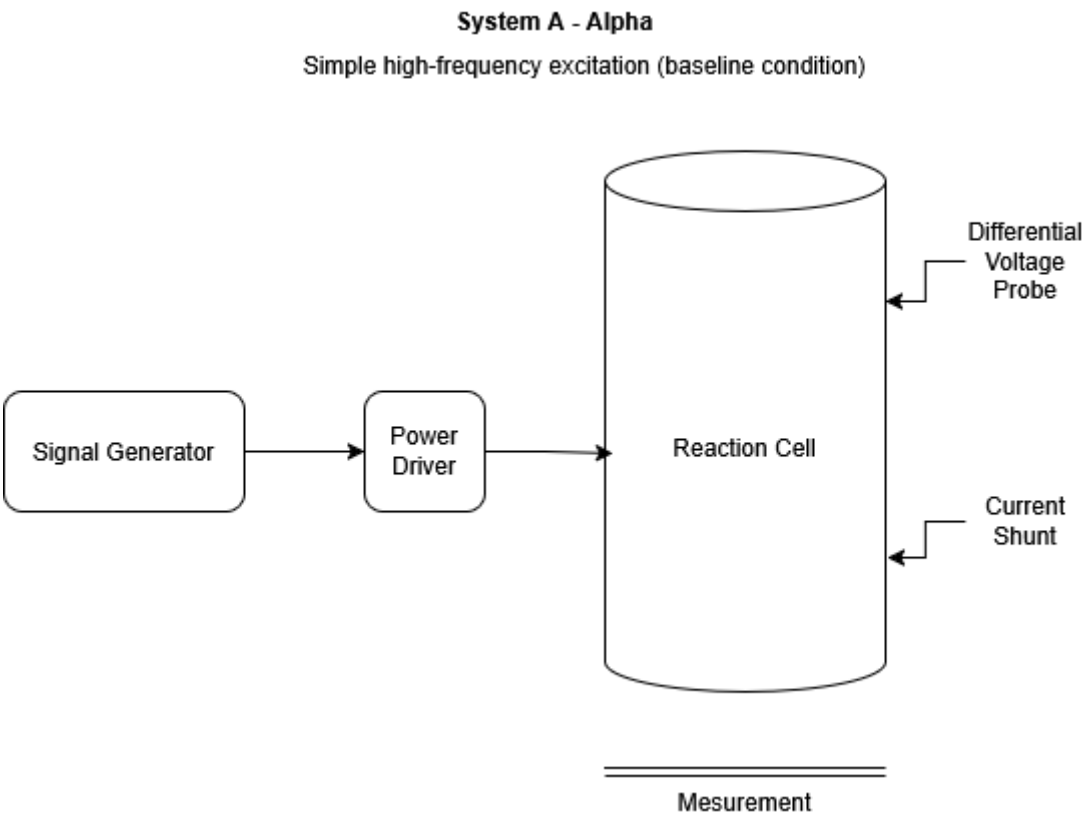
Characteristics:

- Periodic sinusoidal or pulsed excitation
- No structured multi-component timing
- No feedback pathway
- Direct excitation of the driven cell

Fixed parameters:

- Identical electrode geometry
- Identical medium composition
- Identical cell volume
- Identical thermal boundary conditions
- Matched average input power

System A establishes reference behavior under classical resonance tuning.



6.2 System B – Structured Excitation with Passive Feedback

System B introduces two controlled modifications relative to System A:

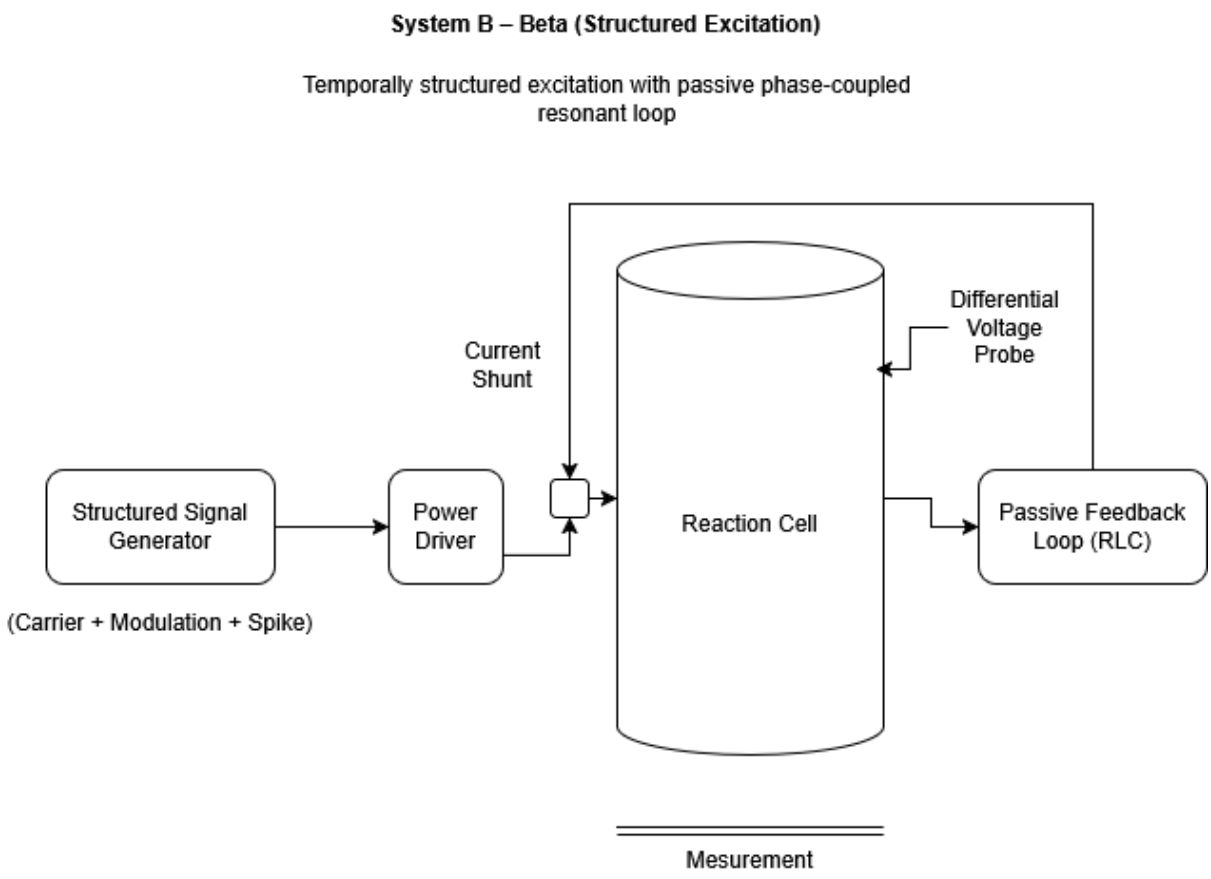
1. Temporally structured excitation
2. Passive phase-selective feedback via RLC pathway

Structured Excitation

The excitation signal consists of coordinated time-domain components, including:

- A primary oscillatory carrier
- Slower modulation structure
- Short-duration transient elements

The waveform does not increase total average power relative to System A.
It redistributes energy temporally.



Passive Feedback

A frequency-dependent RLC network is inserted in the return path.

Properties:

- Q-factor typically in moderate range (Q ≈ 2–5)
- No active control
- No adaptive regulation
- Purely passive phase shaping

The feedback pathway selectively influences phase alignment within defined frequency bands while preserving classical energy conservation.

6.3 Strict Parameter Matching

To ensure experimental validity, the following constraints apply:

- Equal average input power
- Equal RMS voltage where applicable
- Identical electrode surface area
- Identical medium composition and conductivity
- Controlled temperature (±1–2°C)
- Identical measurement instrumentation

Any observed difference must arise from excitation structure and feedback interaction alone.

6.4 Control of Confounding Factors

The experimental design explicitly controls for:

- Thermal drift
- Electrochemical surface modification
- Electrode aging
- Measurement bandwidth limitations
- Power supply variation

Power matching is verified independently of waveform shape to exclude trivial amplitude effects.

6.5 Comparative Evaluation Strategy

Both systems are evaluated under:

- Fixed parameter sets
- Repeated measurement runs (≥10)
- Identical environmental conditions

Primary comparison metrics:

- Phase variance
- Impedance stability
- Coherence Index (KCI)

Only statistically significant and reproducible differences are considered evidence supporting the SRC hypothesis.

Section Summary

Section 6 defines a controlled experimental architecture in which structured excitation and passive feedback are the only systematic variables.

This ensures that any observed differences are attributable to temporal organization and phase-selective coupling rather than uncontrolled system variation.

7. Measurement Methodology

The measurement methodology is designed to ensure that any observed differences between System A and System B are attributable solely to excitation structure and passive feedback interaction.

All measurements are conducted under matched environmental and electrical conditions.

7.1 Electrical Quantities

The following primary quantities are recorded:

- Voltage across the driven element
- Current in the return path
- Instantaneous phase difference $\Delta\phi(t)$

Measurements are performed using synchronized channels with sufficient bandwidth to resolve the highest significant spectral component of the excitation waveform.

Phase variance $\sigma(\phi)$is computed over defined observation intervals.

7.2 Impedance Characterization

Impedance behavior is evaluated through:

- Frequency sweep analysis, or
- Time-domain voltage–current reconstruction

Key observables include:

- Location and stability of impedance minima
- Variability across repeated runs

7.3 Coherence Index Evaluation

The Coherence Index (KCI) is computed from time-resolved power:

$$P(t) = V(t)I(t)$$

Evaluation intervals are kept consistent between System A and System B.

7.4 Statistical Evaluation

Each configuration is tested across ≥10 independent trials.

An observed effect is considered significant only if:

- It exceeds 3σ measurement uncertainty
- It remains reproducible across trials
- It persists under matched average input power

Section Summary

Section 7 defines a minimal but sufficient measurement protocol ensuring that phase stability, impedance behavior, and temporal power consistency are evaluated objectively and reproducibly.

8. Falsification Criteria

The SRC framework is explicitly formulated as a falsifiable hypothesis. It is considered unsupported if controlled experimental evaluation does not demonstrate statistically significant and reproducible differences between System A and System B under matched conditions.

The hypothesis is not supported if any of the following conditions are met:

1. **No measurable reduction in phase variance**
   If $\sigma_B(\phi)$does not differ from $\sigma_A(\phi)$beyond statistical uncertainty.
2. **No stabilization of impedance characteristics**
   If impedance minima and resonance behavior remain statistically indistinguishable between configurations.
3. **No increase in Coherence Index (KCI)**
   If temporal power consistency does not improve beyond measurement noise.
4. **Reduction to classical explanation**
   If all observed differences can be fully explained by conventional steady-state RLC transfer characteristics, amplitude effects, or unmatched input power.

Only effects that persist under strict parameter control and reproducibility criteria are considered evidence supporting the SRC hypothesis.

Section Summary

SRC is validated solely through reproducible, statistically significant differentiation under matched conditions.
If such differentiation is absent, the framework does not provide additional explanatory value beyond classical resonance theory.

9. Relation to Existing Research

Structured Resonant Coupling (SRC) intersects with three established research domains:

1. Impedance-based characterization of electrochemical systems
2. Pulsed or time-varying excitation in electrolysis and plasma processes
3. Relaxation dynamics of dielectric media

9.1 Impedance and Phase-Based Characterization

Electrochemical Impedance Spectroscopy (EIS) provides the established framework for analyzing frequency-dependent impedance, phase behavior, and stability metrics in electrochemical systems. Foundational treatments emphasize small-signal linearization, steady-state frequency-domain analysis, and the interpretation of phase minima and reactive balance [1,2].

SRC differs from conventional EIS usage in that impedance and phase metrics are not used primarily for system identification, but as discriminators between excitation architectures under matched boundary conditions.

9.2 Pulsed and Non-Stationary Excitation

Pulsed electrolysis and time-varying excitation strategies have been investigated in various contexts, including hydrogen production and plasma-assisted processes [3,4]. These studies typically explore efficiency optimization through duty-cycle variation, burst modulation, or transient enhancement effects.

However, pulsed excitation alone has been shown to produce inconsistent or context-dependent results when not rigorously power-matched or statistically evaluated.

SRC differs from such approaches by:

- Defining a structured multi-component excitation architecture
- Maintaining strict average power equivalence
- Providing explicit falsification criteria
- Focusing on dynamical stability metrics rather than efficiency claims

9.3 Dielectric Relaxation and Time-Dependent Media

The dielectric relaxation behavior of water and polar media has been extensively characterized, including Debye-type relaxation processes and frequency-dependent permittivity [5,6].

These works demonstrate that polarization dynamics occur on finite time scales and may influence effective reactive behavior under non-stationary excitation.

SRC builds upon this established physical basis by mapping relaxation considerations into an experimentally testable comparative architecture (System A vs. System B), rather than remaining within spectroscopic characterization alone.

9.4 Conceptual Positioning

SRC does not introduce new physical principles.
It operates fully within classical electromagnetic and circuit theory.

Its contribution lies in formalizing temporal excitation architecture as an experimentally controllable design dimension and linking it to measurable order parameters under matched conditions.

10. Implications and Invitation to Replication

If experimental evaluation confirms the hypotheses formulated in this framework, the primary implication would not be the discovery of new physics, but the identification of a practically relevant design principle.

Specifically, it would suggest that:

- Temporal structuring of excitation signals can influence phase stability in relaxation-dominated systems.
- Passive frequency-dependent feedback may reduce phase variance under certain parameter conditions.
- Time-domain organization could represent an additional optimization dimension beyond conventional steady-state resonance tuning.

Such findings would be relevant to domains involving reactive energy exchange in dielectric or electrochemical media, including high-frequency excitation systems, impedance-controlled processes, and structured power electronics.

If, however, no statistically significant and reproducible differentiation between System A and System B is observed, the framework provides a clear null result: temporally structured excitation does not produce effects beyond classical resonance behavior under the tested conditions. This outcome would equally contribute to clarification within the field.

The present document is released to:

- Establish a clearly defined and falsifiable hypothesis.
- Provide a reproducible comparative architecture.
- Invite independent verification or refutation.
- Encourage transparent reporting of positive or negative results.

A more detailed technical extension of the framework, including extended derivations and implementation considerations, is available separately for researchers interested in deeper examination.

Independent replication is explicitly encouraged.

Practical Perspective (Contextual Outlook)

Structured Resonant Coupling (SRC) is not proposed as a new energy source and does not introduce new physical laws. It is formulated as a structured analytical framework for examining dynamical coupling behavior in driven systems.

If experimentally validated, the relevance of SRC would lie in formalizing temporal excitation architecture and passive phase shaping as additional design variables in systems where resonance and feedback interactions influence stability and efficiency.

Such considerations may be of interest in domains involving:

- resonant power conversion structures
- impedance-sensitive coupling systems
- dynamically regulated reactive networks

The framework does not replace established models in power electronics or control theory. It proposes a complementary structural perspective on phase stability and energy exchange under non-stationary excitation.

Further applicability would depend entirely on experimental verification.

Call to Action

Readers interested in the experimental investigation of the SRC framework are encouraged to consult the accompanying Level-2 technical document, available alongside this publication, which provides the detailed implementation architecture, parameter considerations, and measurement methodology required for practical realization.

Independent replication and critical evaluation are explicitly invited. The framework is designed to be experimentally testable, and its validity depends on reproducible observations under controlled conditions.

Researchers and experimental practitioners are therefore encouraged to implement the described system architecture and to report observed results, whether supportive or contradictory.
